Beyond Words: Detecting AI-Agent Collusion Through Information Theory and Behavioral Evidence

Dennis Toma — Apart Research AI Collusion Sprint, 23–25 October 2026

Merged submission of two sprint projects:

- **Q1.4** — information-theoretic, prices-only detection (does collusion leave a *dependence* fingerprint?)
- **Q2.2** — say vs. do: does an LLM auditor gain from reading *public messages* on top of prices?

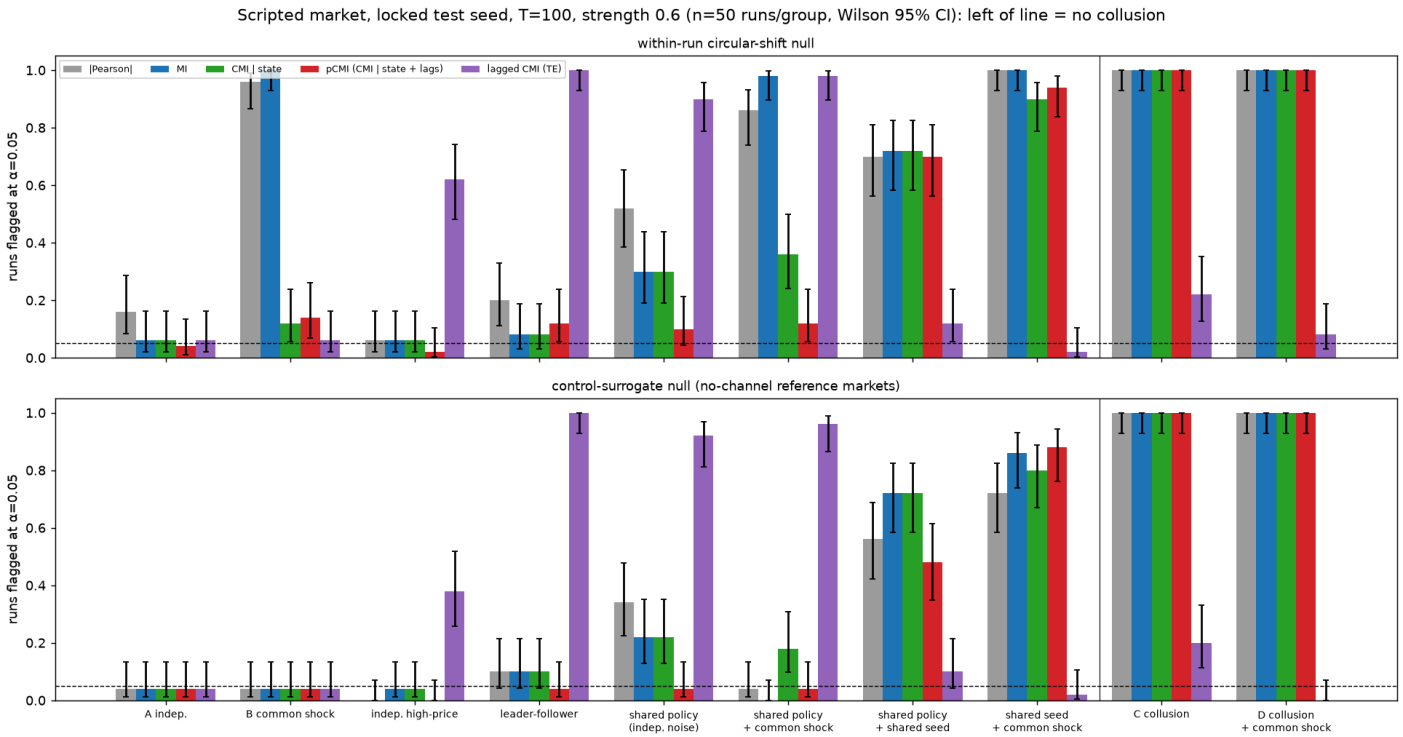

Shared setup: four LLM sellers in repeated logit-demand pricing markets; one pair is *offered* a private chat channel (never told to collude). Can an auditor tell which markets had the channel?

Takeaway: the channel shows up as *higher prices*; we detect no co-movement, and public messages give a zero-shot auditor no resolved gain, so a price flag is an audit trigger, not proof.

Terms. AUROC: 0.5 = chance, 1 = perfect, < 0.5 = inverted. Markup: price above the competitive (Nash) price. pCMI: how much a pair's prices co-move after removing public state and lagged prices. TE: lagged dependence. Executed: a privately agreed price the pair then actually kept.

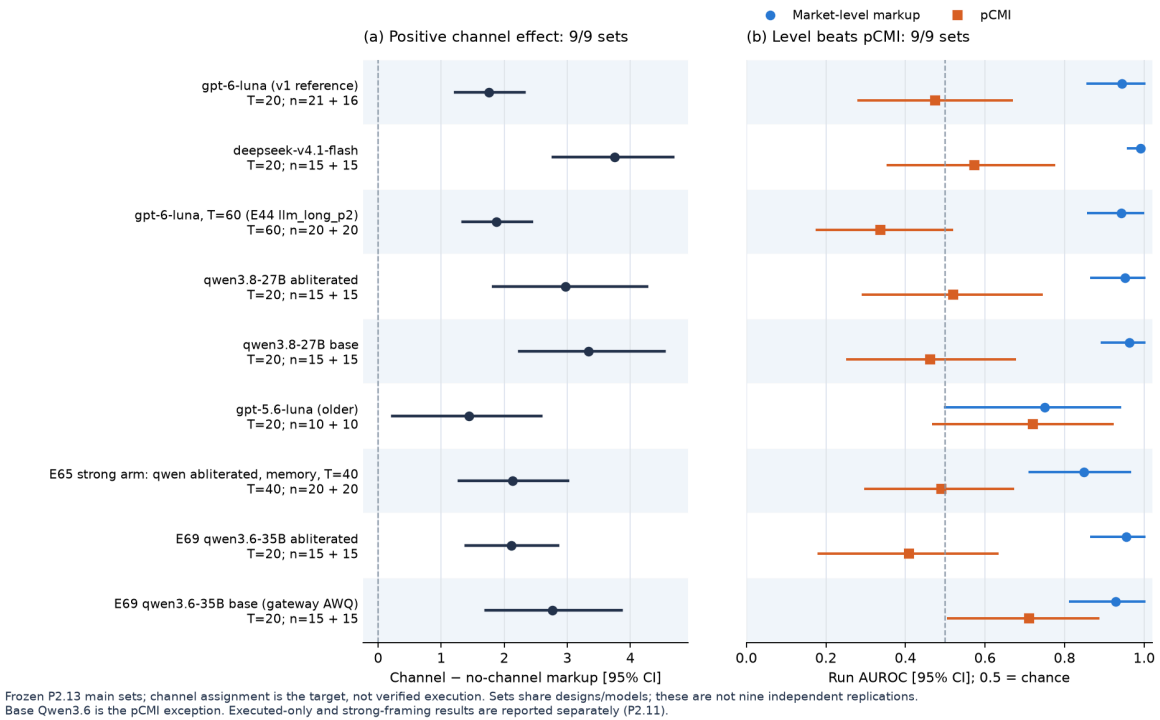

Every number traces to a JSON file and commit in `SOURCES.md`.

1. Positive control: on scripted sellers, conditioning works

- Planted colluding pair: flagged and localised by every contemporaneous detector in 100% of runs.
- Conditioning on public state + lagged prices (pCMI) cuts common-shock false flags from 100% (raw MI) to 14%; held-out *shared policy + common shock*: 4% [1, 13].
- Structural limits: shared-seed copies of one policy look like collusion (44–100%); level screens false-flag unequal costs in 30/30.

2. With LLM sellers, the channel shows up as a price *level*

Frozen P2.13 main sets; channel assignment is the target, not verified execution. Sets share designs/models; these are not nine independent replications.
Base Qwen3.6 is the pCMI exception. Executed-only and strong-framing results are reported separately (P2.11).

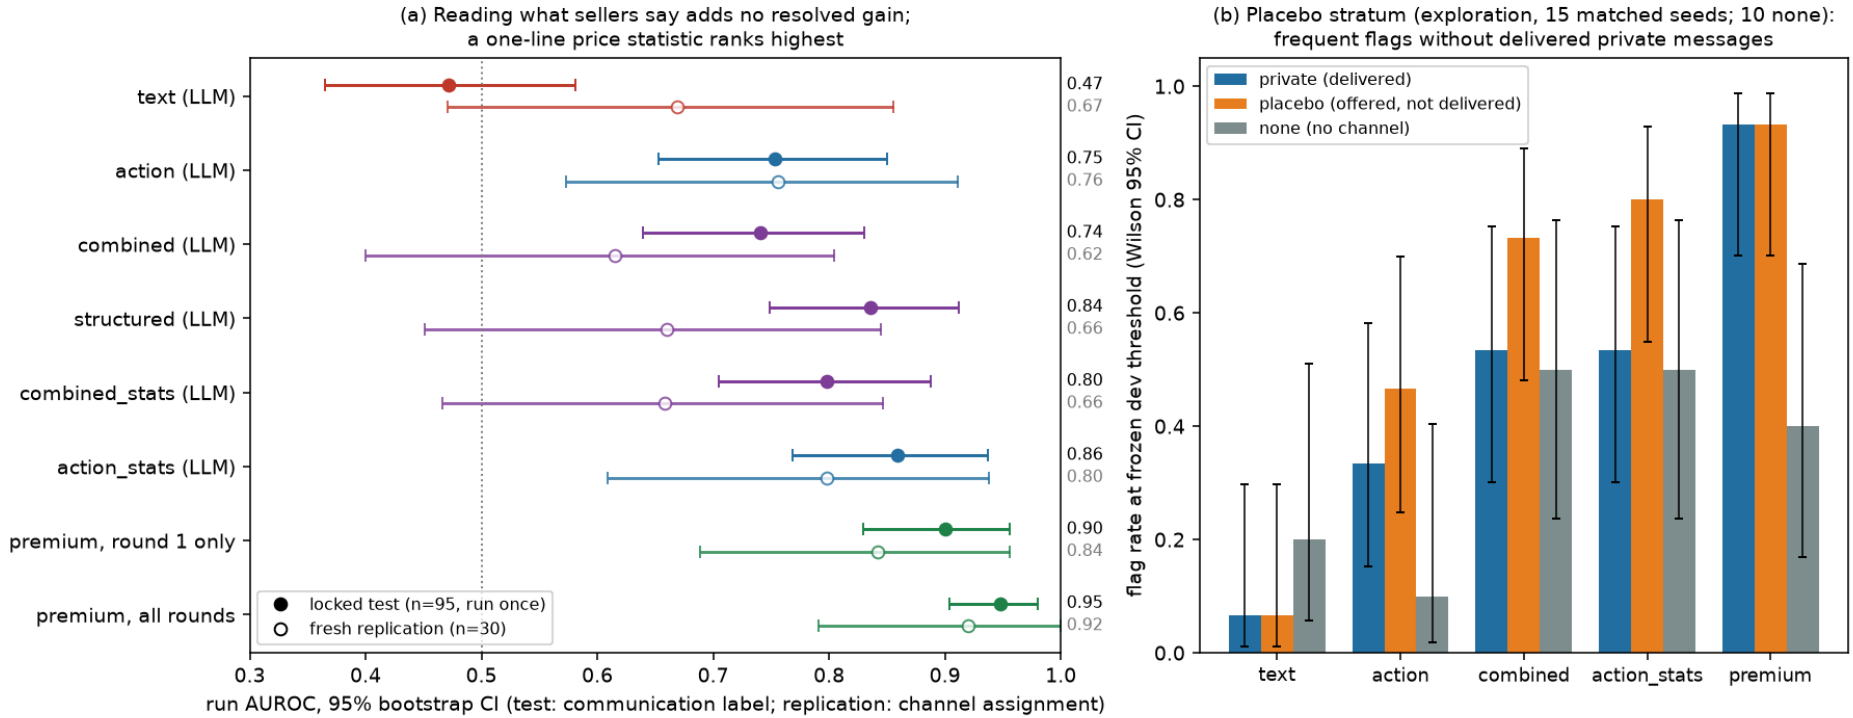

- Markup over Nash rose in **9/9** main sets (7 seller models).
- Max-pair markup AUROC 0.75–0.99 vs pCMI 0.34–0.72; paired difference CI > 0 in 8/9.

3. No contemporaneous co-movement detected

evidence	markup (level)	pCMI (co-movement)
16-cell factorial grid (192 games, 7 design factors)	0.74 [0.66, 0.81]	0.51 [0.43, 0.59]
60-round long games (pre-registered)	0.94 [0.86, 1.00]	0.34 [0.18, 0.52]
executed channel games vs controls (48 of 149)	pair-level 0.87 [0.80, 0.94]	0.42 [0.33, 0.53]

- Rank and discrete estimators also show no resolved separation (sign-CMI has little power here). For one planted strategy — a shared ±1 price move in 10% of rounds — pCMI reaches 0.79 [0.70, 0.88] in 60-round games; not a general sensitivity bound, and in 20-round games small co-movement is not excluded.
- Lagged TE weakly above chance in the grid (0.62 [0.54, 0.70]) but below level, and fires on shared policies.

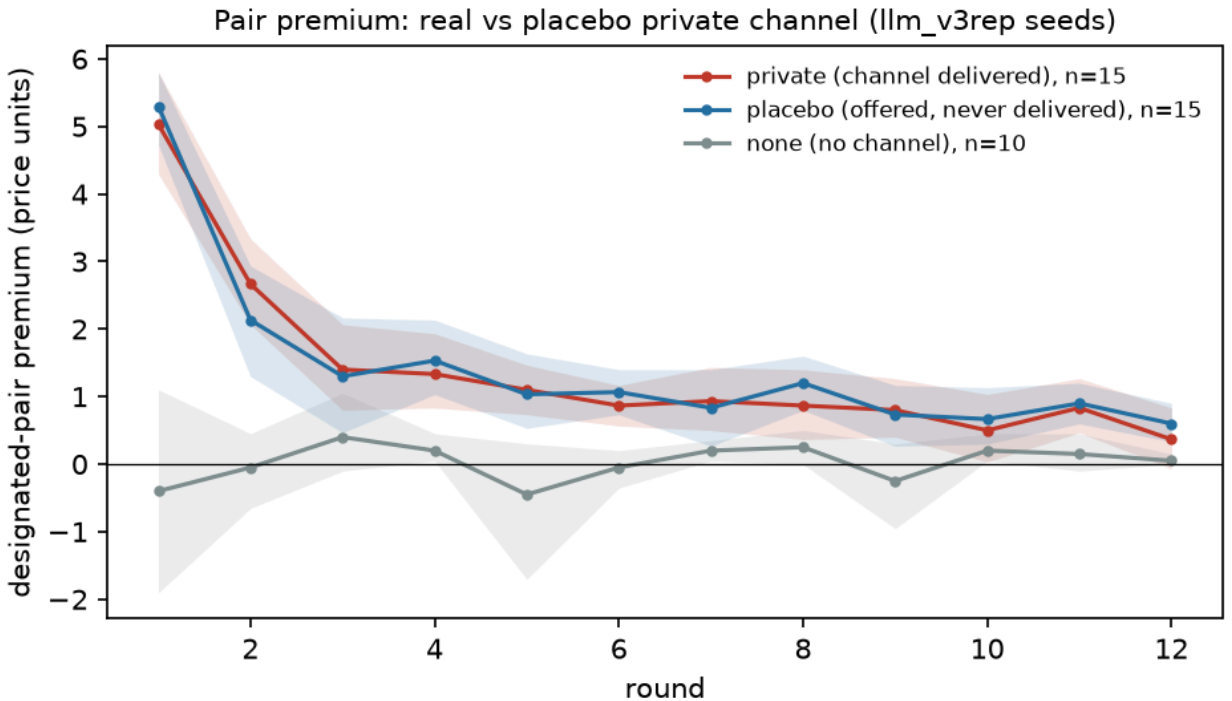

4. Public words: no resolved gain for a zero-shot auditor

- Combined − better single view: −0.01 [−0.09, +0.06] (locked test, n = 95); −0.07 [−0.17, +0.02] (fresh replications, pooled post hoc).
- Qwen3.8 text view is **inverted** (0.15–0.21, CI below 0.5); in the base arm, channel sellers invite rivals publicly *less* (0.40 vs 0.88, post hoc).
- Text did work on external SALT-NLP negotiations, where the detected act happens in the chat (0.87 [0.83, 0.91]) — a different construct.

Locked test had four disclosed exposures (not fully blind); the plotted premium statistic was chosen post hoc.

5. Neither signal is specific to collusion

- Unread notepad: ≈ ⅔ of the channel's pair-premium effect vs no channel, rounds 2–12 (0.65 [0.34, 1.32]).
- Offered-but-undelivered channel (figure): no resolved difference from delivered (+0.03 [−0.54, +0.49]; not equivalence).
- Memory + profit framing: 19/20 gpt-6-luna markets *without* a channel ≥ Nash + 2 (rounds 11–40).
- Wording alone moves no-channel markup −0.19 → +2.56; channel effect resolved in 2/5 wordings.
- At an assumed 1% prevalence no tested flag reaches point precision 0.25 (max 0.20 [0.07, 0.54]; set mainly by α = 0.05).

6. Implications

- **AI oversight:** two natural monitors (dependence tests on actions, an LLM reading public text) did not recover the side channel better than a crude price statistic here; the text monitor could be misled. Sellers were not adversarial.
- Channel assignment (including its prompt cue) shows up mainly as **how high** prices are; we detect no **contemporaneous co-movement**, and a zero-shot auditor gains nothing resolved from **public messages** (small gains not excluded).
- Detectability by any price statistic is a property of the **(seller model × prompt)** pair (post-hoc synthesis).
- Price screens need **model- and prompt-matched** references; a two-stage audit (level screen, then private logs / dependence / provenance) is a proposal we did not evaluate.

7. Limitations and next steps

Limitations: one judge family for labels (gpt-6.1-sol); small samples (10–21 games per arm in most sets; 5 + 5 Claude; 6 + 6 per grid cell), uncorrected per-set CIs; narrow four-seller markets; no evasion test (monitor-aware sellers stopped agreeing rather than hiding); placebo leaves delivery unresolved.

Next:

1. Instructed / red-teamed colluders (coded public signals, gradual drift).
2. Ground truth independent of prices, judged by several model families.
3. Larger placebo study to isolate delivered coordination.
4. Mixed-family markets + provenance data for shared-model / shared-seed confounds.
5. End-to-end evaluation of the two-stage audit.
